ABSTRACT

Background: Autofluorescence bronchoscopy (AF) is more sensitive than white light bronchoscopy (WL) for the detection of bronchial pre-neoplasia, but lacks specificity which necessitates extensive biopsy resulting in longer procedural time. These studies evaluated fiber-optic based systems, and white-light video-bronchoscopy (WLVB) has replaced fiber-optic bronchoscopy more than a decade ago. The advantage of videobronchoscopy lies in delivering clearer images due to incorporation of miniature charge couple device to its tip, however a change of bronchoscope is required if AF is performed after WLVB. Autofluorescence-reflectance imaging is a video-bronchoscope that allows AFVB and WLVB by means of a hand-switch. We compared WLVB against AFVB for the detection of early airway cancer and bronchial pre-neoplasia where the order of procedures and bronchoscopists was random.

Methods: WLVB and AFVB were performed on all high risk patients. Each site was graded as normal, abnormal or suspicious. All abnormal and suspicious areas were biopsied as well as normal appearing second-generation carina as controls.

Results: 570 patients were recruited and 674 airway sites with biopsies were evaluated. WLVB demonstrated 90% sensitivity and 99% specificity for intraepithelial neoplasia (moderate dysplasia or worse) against 97% sensitivity and 94% specificity using AFVB. WLVB was also 100% sensitive and 93% specific for high-grade dysplasia (severe dysplasia or worse) compared with 96% and 86% using AFVB. Kappa agreements between WLVB and AFVB visual grades with pathology were 0.91 ($p<0.001$) and 0.86 ($p<0.001$) respectively.

Conclusion: WLVB performed better than AFVB for high-grade dysplasia and discriminated bronchitis which would otherwise require biopsy with AFVB.

INTRODUCTION

Over 1 million new cases of lung cancer are diagnosed each year and is the leading cause of mortality with more deaths than prostate, breast and colon combined. Five year survival remains dismal at 15% despite strides in radiological imaging, surgical techniques, and chemo-radiotherapy since majority have lymph node or extrathoracic metastases at presentation.[1] Although the potential for lung cancer prevention exists, complete eradication of smoking is difficult and former smokers continue to be at high risk for lung cancer.[2]

Chest computed tomography (CT) screening trials have reported 10 year survival in excess of 80% for stage I tumors if surgically intervened.[3,4] The recent National Lung Screening Trial of more than 53,000 individuals at risk for lung cancer randomized to 3 annual screenings with low dose CT or CXR demonstrated 20% reduction in cancer mortality in favor of low dose CT primarily due to more early stage lung cancers detected.[5]. Chest CT is good for cancers arising from the peripheral airways and lung parenchyma but poor for those involving the central airways.[3,4] Detection of radiographically occult airway cancers represents another potential target since they are accessible to the bronchoscope, and local treatments with photodynamic therapy, high dose brachytherapy, electrocautery, cryotherapy and surgery have yielded favorable survival outcome.[6-10] As these pre-invasive lesions are small, superficial and measuring only few cells thick, they are not easily observed on white light bronchoscopy (WL).[11] The need to identify bronchial pre-neoplasia and carcinoma in-situ (CIS) is important as Bota et al reported that 37% severe dysplasia and 88% CIS progressed to invasive cancer.[12] Most CIS did not resolve spontaneously, and when allowed to progress to invasive cancer they became incurable by local treatments thereby favoring early intervention than expectant observation.[13]

Autofluorescence bronchoscopy (AF) is developed to address this limitation of WL and works on the principle that bronchial epithelium emits intense green autofluorescence when illuminated by blue light.[14] As the epithelium transforms from dysplasia, CIS to invasive cancer a progressive decline in green fluorescence occurs due to increased thickness and neovascularisation. AF has demonstrated superiority over WL for airway dysplasia but lacks specificity since a third of lesions with abnormal

fluorescence represent false-positives on histology.[14-18] Lacking in specificity is problematic as it necessitates extensive biopsy resulting in greater cost, longer procedural time, increased risk of bronchospasm, bleeding from multiple endobronchial biopsies, and more sedation that may compromise patient safety. However these studies evaluated fiber-optic based WL and AF systems,[14-18] and video-bronchoscopy has replaced fiber-optic bronchoscopy more than a decade ago.

The advantage of video-bronchoscopy lies in delivering clearer images due to incorporation of miniature charge couple device (CCD) to its tip. Autofluorescence-reflectance imaging (AFI) is a video-bronchoscope that allows autofluorescence (AFVB) and white-light videobronchoscopy (WLVB) examination by means of a hand-switch. We compared WLVB against AFVB for the detection of early airway cancer and bronchial pre-neoplasia where the order of procedures and bronchoscopists were randomly assigned. Part of the results have been reported in the form of an abstract.[19]

Materials and Methods

The protocol was approved by the institutional review board of Thoraxklinik Heidelberg (reference number 12-2004), and written informed consent was obtained from all patients.

Study Subjects

Included in the prospective randomized study were; (1) current or former smokers suspected of lung cancer scheduled for bronchoscopy; (2) surveillance after curative surgery for stage I and II non-small cell lung cancers (NSCLC), (3) those with previous head and neck cancers as well as (5) high-risk individuals with atypia on sputum cytology but normal CT. Excluded were patients who received photosensitising agents or chemopreventive drugs such as retinoids within 3 months, radiotherapy to chest or cytotoxic chemotherapy within 6 months of bronchoscopic procedure; pneumonia; acute bronchitis; unstable angina; bleeding disorders; pregnancy; and adverse reactions to topical lignocaine.

Methods

AFI (EVIS LUCERA BF –F260, Olympus, Japan) is a video-bronchoscope with a high resolution imaging CCD chip at the distal end which allows the bronchoscopist to change between WLVB and AFVB by means of a hand-switch. The AFVB image is a

composite of 3 signals; autofluorescence (460-690 nm) with blue excitation light (395-445nm); green and red light signals from respective green (550nm) and red (610nm) wavelengths. Hemoglobin in the blood vessels absorbs green light, and dysplasia would appear magenta, bronchitis blue and mucosal bleeding dark blue.

Each patient underwent both WLVB and AFVB. The order and bronchoscopists were randomized using random number generator in Microsoft Excel (Microsoft Corp, Redland, WA) such that 1 bronchoscopist was assigned only 1 procedure per patient. The bronchoscopists (RE, FH) performed airway examinations independently and recorded areas of visual abnormalities according to Table 1 in digital and video formats. After both examinations, biopsy was performed for areas recorded as abnormal and suspicious jointly by the bronchoscopists in addition to one control biopsy over the second generation carina. In those with normal WLVB and AFVB, 1 control biopsy was obtained from second-generation carina per patient. All biopsy specimens were evaluable as there was sufficient bronchial epithelium and interpreted by a dedicated lung pathologist who was blinded to the bronchoscopic findings in accordance to the International Histological Classification of Tumors [20] as (1) normal; (2) inflammation/bronchitis; (3) hyperplasia; (4) squamous metaplasia; (5) mild dysplasia; (6) moderate dysplasia; (7) severe dysplasia; (8) carcinoma in situ (CIS); or (9) carcinoma.

Statistics

For the purpose of statistical analysis, physicians' visual classification was converted to a two-point scale where classes 1 and 2 became ‘‘negative’’ and class 3 became “positive’’. Final pathological diagnosis was also converted to a two point scale where “mild dysplasia and below” became ‘‘negative’’ and “moderate dysplasia and worse” became ‘‘positive’’. Sensitivity, specificity, positive predictive and negative predictive values of WLVB and AFVB were calculated. Correlation of the visual grade with pathology was determined by Spearman rho test, values were expressed as median and inter quartile range, and $p < 0.05$ was considered statistically significant.

Results

The study included 329 males and 241 females of which 162 were current or former smokers suspected of lung cancer; 312 for surveillance after curative surgery for

stage I and II NSCLC; 54 with previous head and neck cancers and 42 with suspicious sputum cytology. The median age was 55 years (range, 48-63) and 40 pack years' of smoking (range, 38-44). Six hundred and seventy-four airway sites and biopsies were evaluated (Table 2).

Intra-epithelial neoplasia defined as moderate dysplasia or worse was identified in 143 biopsies (21%): 23% from current or former smokers suspected of lung cancer; 57% from surgically resected lung cancer subjects on surveillance; 12% from head and neck cancer patients; and 8% with sputum atypia. Sensitivity and specificity for its detection using WLVB and AFVB were 90%, 99%, and 97%, 94% respectively. Positive and negative predictive values with WLVB and AFVB were 96%, 97%, and 82%, 99%.

High-grade dysplasia defined as severe dysplasia or worse was found in 90 biopsies (13%): 22% from former and current smokers suspected of lung cancer; 56% from surgically resected lung cancer patients; 15% from head and neck cancer subjects; and 7% with sputum atypia. Sensitivity and specificity for its detection using WLVB and AFVB were 100%, 93% and 96%, 86% respectively. Positive and negative predictive values with WLVB and AFVB were 67%, 100% and 51%, 99% (Table 2). Sixty-eight airway sites (10%) graded suspicious by WLVB and AFVB had biopsies confirming carcinoma and CIS that were CT occult: 22% in current and former smokers; 56% in surgically resected lung cancer patients; 15% in head and neck cancer subjects; and 7% with sputum atypia.(figure 1,2)

Relative sensitivity of AFVB over WLVB was 1.07 for the detection of early airway cancer and bronchial pre-neoplasia. The physicians' visual classification by WLVB and AFVB correlated well with pathology: WLVB $r=0.91$, $p<0.001$ and AFVB $r=0.86$, $p<0.0001$. WLVB and AFVB graded all CIS and carcinomas suspicious. For severe dysplasia lesions, all 22 were graded suspicious by WLVB compared to 18 by AFVB. AFVB scored all 53 lesions with moderate dysplasia suspicious compared to 40 by WVB (Tables 3,4).

Value of AFVB when WLVB normal

Of the 423 sites that were graded normal by WLVB, 29 were graded abnormal (pathology: 16 normal, 13 squamous metaplasia) and 18 suspicious (pathology: 5 mild dysplasia and 13 moderate dysplasia) by AFVB. Addition of AFVB to normal WLVB led

to increased detection of moderate dysplasia, mild dysplasia and squamous metaplasia (figure 3,4).

Value of AFVB when WLVB abnormal

Two hundred and fifty one sites were graded abnormal and suspicious by WLVB. All 40 moderate dysplasia lesions appeared suspicious with AFVB compared to 39 with WLVB. WLVB graded all 90 sites of severe dysplasia, CIS and carcinoma suspicious compared with 86 suspicious sites by AFVB. Twenty-one out of 45 sites showing inflammation were graded suspicious with AFVB and abnormal due to bronchitis by WLVB. The addition of AFVB to abnormal WLVB identified 1 more site of moderate dysplasia but more inflammatory lesions that necessitated biopsy (Table 5).

Discussion

A multimodality approach that incorporates chest CT and bronchoscopy is necessary to assure a successful early lung cancer detection program. Early central lung cancers can be invisible, hypertrophic, nodular, polypoid or mixed. The hypertrophic lesion is the dominant type and may pose a challenge for WL since it only shows subtle mucosal changes and measures less than 1.5 mm thick.[21] It is a good target for AF as increased mucosal thickness and vascularity lead to reduced fluorescence in the background of normal green fluorescence. Previous studies with lung imaging fluorescence endoscopy (LIFE), D-Light and SAFE 1000 have reported relative sensitivities of 2 to 6.4 over WL for intra-epithelial neoplasia.[14-18,22] However the lower WL sensitivity is attributed to inferior fiber-optic based systems used in the studies, and videobronchoscopy has replaced fiber-optic bronchoscopy more than a decade ago. Chhajed et al demonstrated improved sensitivity for airway dysplasia using the videobronchoscope (sensitivity 72%, specificity 53%), but a change of scope was required which caused patient discomfort and inconvenience to the bronchoscopist.[23] Low specificity associated with AF was problematic particularly in distinguishing pre-neoplastic lesions from bronchitis, which could lead to unnecessary biopsy, longer procedural time, increased risk of bronchospasm, bleeding from multiple endobronchial biopsies and need for additional sedation that may compromise patient safety. Lee et al reported 86% sensitivity and 94% specificity with SAFE 3000 (Pentax, Japan) that displayed real-time video and AF images of the lesion side by side. Dual imaging

provided anatomic and functional information of the area of interest and was useful in diagnosing bronchitis, previous biopsy site and fibrosis following endobronchial therapy.[24]

Our prospective study is the largest with significant number of evaluable biopsies where the order of procedures (WLVB, AFBV) and bronchoscopists were randomized. We showed that WLVB was as good as AFVB for detection of early lung cancer and bronchial pre-neoplasia (relative sensitivity of AFVB over WLVB 1.07). WLVB was superior in discriminating bronchitis where AFVB led to increased biopsy. AFVB had a strong negative predictive value, and adding AFVB to WLVB enhanced the detection of moderate dysplasia, mild dysplasia and squamous metaplasia. Seven and 3 sites of squamous metaplasia were graded suspicious by WLVB and AFVB respectively. The significance of this finding is unclear at the time of writing since longitudinal follow up of these lesions is underway. Breuer and coworkers challenged the concept of squamous cell carcinogenesis by reporting rapid and non-stepwise progression in 3 (9%) squamous metaplasias with suspicious autofluorescence to CIS or invasive carcinomas within 4 to 7 months.[25] These lesions were subsequently discovered to possess DNA copy number alterations that were distinct from squamous metaplasia with normal autofluorescence and did not progress.[26]

Conclusion

Incorporating high definition color CCD chip to the bronchoscope tip provides WLVB images comparable to AFVB for the detection of bronchial pre-neoplasia and early central cancers, and better discriminated bronchitis which would otherwise require biopsy. AFVB where available improves identification of moderate dysplasia that carries 11% risk of progression to invasive carcinoma,[27] and may complement WLVB in the pre-surgical evaluation of patients with early lung cancers for synchronous CIS and intra-epithelial neoplasia as well as margin assessment of these cancers before resection.[28] Our study adds robust data in support of recent lung cancer guidelines recommendations for WLVB as the first modality in the evaluation of patients with sputum atypia, for surveillance of subjects harboring bronchial severe dysplasia or CIS as well as for synchronous lesions in those with early lung cancers undergoing surgery.[29]

Table 1: Visual Classificaton of Bronchoscopic findings with WLVB and AFVB

Class	WLVB	AFVB
1/ Normal	No visual abnormality	Negative (Green)
2/ Abnormal	Erythema, swelling or thickening of bronchial mucosa, airway inflammation and fibrosis	Negative (Blue)
3/ Suspicious	Nodular, polypoid lesions, irregular bronchial mucosa, focal thickening of the subcarina	Positive (Magenta)
